Major Galaxy Mergers and the Growth of Supermassive Black Holes in Quasars

Ezequiel Treister,1,4 Priyamvada Natarajan,2,3,4* David B. Sanders,1 C. Megan Urry,2,3,4 Kevin Schawinski,3,4 Jeyhan Kartaltepe1,5

Despite observed strong correlations between central supermassive black holes (SMBHs) and star formation in galactic nuclei, uncertainties exist in our understanding of their coupling. We present observations of the ratio of heavily obscured to unobscured quasars as a function of cosmic epoch up to \( z \approx 3 \) and show that a simple physical model describing mergers of massive, gas-rich galaxies matches these observations. In the context of this model, every obscured and unobscured quasar represents two distinct phases that result from a massive galaxy merger event. Much of the mass growth of the SMBH occurs during the heavily obscured phase. These observations provide additional evidence for a causal link between gas-rich galaxy mergers, accretion onto the nuclear SMBH, and coeval star formation.

When unobscured quasars (1) have been known for a long time (2) and their statistical properties are well studied (3), the numbers of the heavily obscured quasar population and its variation with cosmic epoch are still strongly debated. This population has been uncovered with mult wavelength selection techniques that simultaneously exploit x-ray (4), optical (5), and mid-infrared (mid-IR) (6) wavelengths. As a result of the efficiency of these techniques, the sample sizes of obscured quasars are growing substantially. The existence of a large number of heavily obscured quasars at \( z \approx 2 \) was predicted by early active galactic nuclei (AGN) population synthesis models that successfully explain the generation of the x-ray background (7). However, their space density cannot be constrained by these calculations (8). What population these obscured sources evolve into or proceed from is poorly understood at present.

The link between ultraluminous infrared galaxies (ULIRGs) and quasars was first suggested by Sanders et al. (9). There is substantial observational evidence that ULIRGs, at least locally, are the product of the gas-rich merger of two massive \([ M > 10^{11} M_{\odot} \text{ (solar mass)} ]\) galaxies (10). The merger process is believed to switch on accretion onto the central black hole as it provides efficient transport of gas to the nucleus (11). The gas funneled to the center is expected to fuel the supermassive black hole and induce star formation. The origin of the infrared luminosity of these sources, whether they are powered primarily by star-formation processes (12) or the AGN (9) activity, is still debated. Here, we present recent measurements of the space density of heavily obscured quasars as a function of redshift and estimate the duration of the obscured stage by comparing models with observations.

Mainly due to the effects of dust and gas obscuration at most wavelengths, finding heavily obscured quasars (13) is a challenging task that has prevented the identification of larger samples, in particular, at high redshifts. Measuring their space density is even more difficult, as it requires a good knowledge of the selection function and observational biases. We have compiled observations of obscured quasars selected at various wavelengths using different techniques, described in detail in the supporting online material (SOM), including spectral fitting in x-rays (14) and IR selection (15–17). X-rays, especially at rest-frame energies greater than 10 keV, are not appreciably affected by obscuration. In addition, most of the absorbed energy is later reemitted at IR wavelengths. Thus, these techniques permit an estimate of the number of heavily obscured quasars at \( z > 1 \). In the local universe, the space density of ULIRGs (18), which can be used as an indicator of the total number of quasars, implies that the ratio of heavily obscured to unobscured quasars at \( z = 0.1 \) is \( \sim 1 \) (Fig. 1).

Both in the local universe and at \( z \approx 1 \), heavily obscured AGN are bright at mid- and far-IR wavelengths and also potentially in the submillimeter-wavelength range but are optically faint (Fig. 2). At low redshift, the ULIRG is clearly the product of a galaxy merger, whereas at high redshift a merger is suggested, but deeper data are needed to confirm this hypothesis. The rest-frame optical images of six heavily obscured quasar candidates show indications of ongoing major mergers and interactions (Fig. 3).

To interpret these observations and the evolution of these populations, we started with the standard ansatz that the gas-rich major merger of two massive galaxies produces one newly fueled quasar. This triggered quasar is originally obscured by the surrounding gas and dust (9), in some cases reaching Compton-thick levels (i.e., where the optical depth for Compton scattering is greater than one). After a time \( \Delta t \approx 10^2 \) to \( 10^3 \) years (19), which we estimate independently below, most of the dust and gas are removed from the central region and the quasar becomes unobscured.

To test this simple prescription, the calculated ratio of heavily obscured to unobscured sources from merger rates of massive gas-rich galaxies needs to match the observed ratio of obscured to unobscured quasars. This ratio can be calculated using the merger rate as a function of cosmic time in the context of the hierarchical cold dark matter (LCDM) structure formation paradigm. Using the assumptions described above, we estimated the ratio of obscured to unobscured sources as

\[
\frac{N_{\text{obsc}}(z)}{N_{\text{unobsc}}(z)} = \frac{\Delta t \frac{dN}{dt} \frac{d\lambda}{dN}(L_{\text{gal}}(z)) f_g(z)}{N_{\text{unobsc}}(z)}
\]

where \( N_{\text{obsc}}(z) \) is the space density of heavily obscured quasars; \( dN/dt \frac{d\lambda}{dN}(L_{\text{gal}}(z)) f_g(z) \) is the merger frequency per galaxy per unit time; \( N_{\text{gal}} \) and \( N_{\text{unobsc}} \) are the space densities of massive galaxies and unobscured quasars, respectively; and \( f_g \) is the observed ratio of obscured to unobscured quasars as a function of redshift. Measurements of the space density of obscured quasars at high redshift were obtained from x-ray (green triangles (14)) and mid-IR imaging (blue pentagon (16) and black squares (17)) and spectroscopy (brown circle (15)) selection techniques. For the \( z \approx 0 \) measurement, we used the luminosity function of local ULIRGs (18), assuming that each ULIRG is either a heavily obscured or an unobscured quasar. The solid black line shows the heavily obscured to unobscured quasar ratio expected from AGN luminosity functions derived from hard x-ray observations (32), and the solid red line corresponds to the ratio obtained if every gas-rich major merger of two massive galaxies generates a heavily obscured quasar, which after a time \( \Delta t \approx 96 \) My becomes unobscured. Dashed lines show the uncertainty in this relation, at the 90% confidence level.

the average fraction of gas-rich galaxies. The major merger frequency per galaxy in the LCDM paradigm can be parameterized as a power-law in $(1 + z)$ with a mass-dependent exponent of $\approx 1.5$ (20). This form is derived from model parameters constrained by observations. To estimate the space density of galaxies above a threshold stellar mass, we used the median mass measured for ULIRGs found in the Cosmic Evolution Survey (COSMOS). The median mass increases with decreasing redshift, going from $\sim 10^{11} M_\odot$ at $z \approx 2$ to $10^{11.3} M_\odot$ at $z = 0.8$ (fig. S1). We then incorporated this limiting mass into the stellar mass function computed by Marchesini et al. (21) to obtain the space density of massive galaxies as a function of redshift. Rather than directly estimate the gas content of high-redshift galaxies, which is currently observationally impossible at these redshifts, we used the average star-formation rate as a proxy for the evolution of the fraction $f_\text{g}$ of gas-rich galaxies. The evolution of the star-formation rate can be approximated as $(1 + z)^2$ up to $z \approx 2$, remaining mostly flat at higher redshifts, on the basis of ultraviolet observations of galaxies up to $z \approx 2.5$ (22). Finally, the space density of unobscured quasars, $N_\text{unobsc}(z)$, has been measured by both x-ray (23, 24) and optical (25) surveys, and consistent results are found with these two methods. These are all the ingredients needed to compute the expected fraction of obscured to unobscured quasars, wherein $\Delta z$ in Eq. (1) can be determined as a free parameter. The redshift dependence of each of these components is shown in fig. S2.

The estimates from our simple scenario are consistent with the observations (Fig. 1), in particular considering the steep evolution in the relative number of obscured sources from $z = 1.5$ to 3. This rapid increase is not predicted or expected from existing AGN luminosity functions (Fig. 1). That is, extrapolations from the behavior of less-obscured lower-luminosity sources (with observed column densities $< 10^{25}$ cm$^{-2}$) do not match current observations, in particular at $z > 2$. This suggests the existence of a different channel for the triggering mechanism for quasars, compared to lower-luminosity AGN. The best-fit value of $\Delta z$ we obtained is $96 \pm 23$ million years (Myr; 90% confidence level). This is very similar to the current best estimates of quasar lifetimes in their optically bright, unobscured phases [10 to 100 Myr (26)], indicating that these sources spend roughly half their life in the obscured phase.

Having determined that quasars that are fueled by the merger of massive gas-rich galaxies spend comparable amounts of time in the obscured and unobscured phases, we then estimated the implications for the mass accretion onto the nuclear supermassive black holes during these two stages. Assuming a typical accretion efficiency of $\epsilon = 0.1$, the mass growth of the supermassive black hole due to accretion is given by

$$\Delta M_{\text{BH}} = 1.6 \times 10^7 \left( \frac{L_{\text{bol}}}{10^{45} \text{ erg/s}} \right) \left( \frac{T}{10^8 \text{ years}} \right) M_\odot$$

(2)

where $T$ is the duration of the entire accretion episode that includes the obscured and unobscured phases. The typical bolometric luminosities of these sources span the range $10^{45}$ to $10^{47}$ erg/s [$\sim 10^{12}$ to $10^{14} L_\odot$ (solar luminosity)], while they have black hole masses of $M_{\text{BH}} \approx 10^8$ to $10^{10} M_\odot$ (27, 28). Given that the typical duration of the total (both obscured and unobscured) luminous quasar phase is $T \sim 2 \times 10^8$ years, it is possible for a quasar to build most or all of the black hole mass in a single event, which is triggered by a major merger as suggested here.

In spite of copious accretion, due to their high redshifts and strong absorption, this unexpected population of obscured quasars is not key contributors to the extragalactic x-ray background radiation. Their total contribution is estimated to be $\sim 1$ to
Conversion of Sugars to Lactic Acid Derivatives Using Heterogeneous Zeotype Catalysts

Martin Spangsberg Holm,1,2,3* Shunmugavel Saravanamurugan,1,2* Esben Taarning2,3†

Presently, very few compounds of commercial interest are directly accessible from carbohydrates by using nonfermentive approaches. We describe here a catalytic process for the direct formation of methyl lactate from common sugars. Lewis acidic zeotypes, such as Sn-Beta, catalyze the conversion of monosaccharides and disaccharides that are dissolved in methanol to methyl lactate at 160°C. With sucrose as the substrate, methyl lactate yield reaches 68%, and the heterogeneous catalyst can be easily recovered by filtration and reused multiple times after calcination without any substantial change in the product selectivity.

Carbohydrates represent the largest fraction of biomass, and various strategies for their efficient use as a commercial chemical feedstock are being established in the interest of supplementing, and ultimately replacing, petroleum (1–4). The thermal instability of carbohydrates is a major obstacle in this regard, and biochemical processes have proven to be more applicable than catalytic ones, in part because of their ability to operate at lower temperatures. On the other hand, catalysis often presents improved process design options, resulting in higher productivity and reduced costs related to product work-up. Indeed, catalysis has proven to be scalable and able to supply numerous low-cost products from petroleum.

In contrast to the case for biochemical processes, relatively few products are directly obtainable from carbohydrates by using catalysis. Gluconic acid and sorbitol can be obtained from glucose by oxidation and hydrogenation, respectively, and acidic catalysts are currently being examined for the direct production of 5-hydroxymethylfurfural (HMF) (5–7). However, currently the production of fuels and value-added compounds from carbohydrates is dominated by fermentative processes (8). An important example is the fermentation of glucose to lactic acid, which is used for the production of biodegradable plastics (9, 10) and solvents (11, 12). Lactic acid has also been investigated as a precursor to the production of a wide range of useful compounds through catalytic transformation (13, 14). However, the future role of lactic acid will largely depend on its production costs. Because the fermentation of glucose to lactic acid
